Delegating relational contracts
to corruptible intermediaries

Marta Troya-Martinez and Liam Wren-Lewis*

May 24, 2016

Abstract

This article explores the link between productive relational contracts and corruption. Responsibility for a contract is delegated to a supervisor who cares about both production and kickbacks, neither of which are explicitly contractible. We characterize the optimal supervisor-agent relational contract and show that the relationship between joint surplus, kickbacks and production is nonmonotonic. Delegation may benefit the principal when relational contracting is difficult by easing the time inconsistency problem of paying incentive payments. For the principal, the optimal supervisor has incentives that are partially, but not completely, aligned with her own.

JEL classifications: D73, D86, L14.

Keywords: Relational contracts, delegation, corruption.

Any remaining errors are our own.
A wide range of important economic activities depend on self-enforcing contracts.\footnote{For instance, Antràs and Foley (2015) and Macchiavello and Morjaria (2015) provide evidence that relational contracts play an important role in international supply chains, while Board (2011) and Spagnolo (2012) attest to their value in public procurement. Gibbons and Henderson (2013) and Blader et al. (2015) argue that variation in effective relational contracts within firms can explain significant differences in performance.} Responsibility for these contracts is frequently delegated to intermediaries; firms delegate to managers, governments to bureaucrats. Recent papers suggest that, although delegation can improve productivity, it is often held back by a lack of trust (Bloom, Sadun and Van Reenen, 2012; Bloom et al., 2013). In particular, organizations fear that intermediaries may extract kickbacks in the form of bribes or nonmonetary private benefits. These forms of corruption cannot be legally enforced, and they are therefore also sustained by relational contracts.

If intermediaries are corruptible, how and when should relational contracts be delegated? This paper answers this question by extending a standard principal-agent relational contracting model to include an intermediary supervisor. We characterize the optimal relational contract between the supervisor and the agent and show that, if there is a cap on the payments that the supervisor can authorize, effort can be a nonmonotonic function of discounted surplus. This differs from standard models of relational contracting, where greater surplus within the relationship leads to greater agent effort (Malcomson, 2013). When the supervisor is unconstrained by the payment cap, greater surplus sustains greater payments to reward the agent, inducing higher kickbacks and also greater effort. But, when the supervisor is constrained by the payment cap, she may pay the agent even when he is unsuccessful, increasing kickbacks but reducing effort. Thus, depending on the surplus in the supervisor-agent relationship, there may or may not be a trade-off between encouraging production and reducing corruption.

A further important contribution of the paper is to analyze the costs and benefits of delegation for the principal. We find that, because the supervisor cares less than the principal about payments to the agent, delegation enhances credibility. A supervisor who cares too little about payments, however, will overpay in exchange for kickbacks. The principal therefore faces a trade-off when deciding how much the supervisor’s payoffs should be aligned with her own. Overall, corruption makes delegation costly for the principal, but when relational contracts are difficult this cost may be more than compensated for by
the supervisors greater credibility.

The paper begins in Section 1 by motivating our model through documenting the wide relevance of relational contracts that sustain both production and corruption. We give examples of the kind of trade-offs that can exist and highlight suggestive evidence that kickbacks can help to sustain productive relational contracts.

Section 2 then sets out the model, which is an extension of a moral hazard version of Levin (2003). In the model, a supervisor and an agent may contract relationally over an infinite number of periods. A principal sets the parameters of this interaction at the beginning of the game and then takes no further action. Each period, the agent exerts continuous hidden effort towards producing a binary output that is then split between the supervisor and principal. In return, the agent receives compensation that is partly at the discretion of the supervisor. The part that the supervisor has control over - the ‘bonus’ - is subject to a cap. The supervisor and agent can also exchange noncontractible side payments. To our knowledge, this is the first paper to build a model where productive and corrupt relational contracts co-exist.

A first insight from the model is that the two parts of the relational contract interact with each other in important ways. There is a positive interaction, as the expected stream of future kickbacks allows the supervisor to credibly promise higher bonuses, and these bonuses may then be used to motivate greater effort. But there is also a negative interaction, as, when self-enforcement is a binding constraint, the supervisor must trade off inducing effort and sustaining bribery.

In Section 3 we then characterize optimal relational contracts between the supervisor and the agent. Stationary contracts are optimal and the supervisor may motivate effort using variation both in bribes and in bonuses. The choice of motivation tool and the effort that results depend on the discounted surplus that is shared between the supervisor and agent. When surplus is very high, self-enforcement is not a problem, and the supervisor will always authorize the maximum possible bonus and motivate effort through variation in bribes. When surplus falls below a certain level, the optimal contract may also involve variation in bonuses. This is because the supervisor only pays for part of the cost of

\[2\text{An important assumption in our model is that the supervisor can receive a share of the profit directly, but the agent cannot. We discuss a potential justification of this assumption at the end of Section 2.}\]

\[3\text{The terms side payments, bribes, and kickbacks are used interchangeably.}\]
any bonus, and it is therefore more credible for the supervisor to motivate effort through bonuses rather than bribes. Indeed, when surplus is low, bribes will not be used to motivate effort.

A notable result that follows is that the agent’s effort is nonmonotonic in the joint supervisor-agent surplus. This is because increasing surplus can have two potentially conflicting effects on effort: it raises the amount of effort it is possible to induce, but it may also change the supervisor and agent’s marginal benefit of effort. When surplus is low, bonuses are used to motivate effort, and hence one benefit of higher effort is that it increases the expected bonus. When surplus is high, bonuses are paid regardless of output, and hence this benefit of effort disappears. Thus the supervisor and agent desire a higher level of output when surplus is lower. Overall, an increase in surplus can lead to a decrease in effort.

This result has important implications for policies designed to reduce fraud or corruption in contexts where relational contracts are valuable. Many such policies involve disrupting relational contracts, for instance by encouraging competition or increasing personnel rotation. The results of our theoretical analysis suggest that, in some circumstances, weakening supervisor-agent relations may simultaneously cut corruption and improve output. In other circumstances, however, there will be a trade-off.

Section 4 then analyzes how and when the principal should delegate. We allow the principal to set the fixed transfer paid to the agent, the limit on discretionary bonuses, and the extent to which the supervisor’s preferences are aligned with her own. We find that the principal should choose the supervisor’s preferences to be partly, but not completely, aligned with her own. More aligned preferences make supervisor-agent relational contracting more difficult, and hence the principal has to give them more surplus. Indeed, a supervisor with exactly aligned preferences will never be optimal, because reducing effort slightly below first best is a second-order cost for the principal, but giving up surplus is first-order. On the other hand, less aligned preferences make the supervisor more tempted to pay bonuses regardless of output. At the limit, a supervisor who doesn’t care at all about profits will induce no effort. The optimal supervisor therefore always lies somewhere between the two extremes.

We then show that delegating to a corruptible supervisor can sometimes, but not always, improve the principal’s payoff. The supervisor has a compara-
tive advantage in enforcing relational contracts because she has more credibility when paying promised bonuses. She cares less about making payments and yet values the relationship with the agent because of the expected stream of future kickbacks. Looking at it another way, if the supervisor reneges on her promises, then the agent can punish her by withholding the kickback. If principal-agent relational contracting is difficult, then delegating induces higher effort and increases the principal’s payoff. On the other hand, if relational contracting is easy, then the principal prefers not to delegate in order to avoid having to share part of the surplus with the supervisor.

We consider a number of alternative specifications and extensions in Section 5 of the paper. These include giving the supervisor a more general payoff function and making side payments costly. We show that giving the principal extra instruments can allow kickbacks to be replaced by direct payments and make delegation more advantageous, but that first-best effort will only be induced if we allow seemingly unrealistic contracts. Finally, Section 6 concludes by considering avenues for future theoretical and empirical work. Mathematical proofs of all lemmas and propositions are then given in the appendix.

This article fits into an increasing body of work on relational contracts; Malcolmson (2013) provides a useful survey. Models in this literature have so far focused on situations with only two players and, when considering delegation, have concentrated on delegation to the agent (Alonso and Matouschek, 2007; Goldlücke and Kranz, 2012; Li, Matouschek and Powell, 2016). Such models cannot consider corruption, which is typically modeled as involving collusion between an agent and an intermediary against the interests of a principal.4

A recent paper that considers how delegated cooperation can be maintained is that of Hermalin (2015). He builds a model whereby ‘wining and dining’ helps sustain a productive relationship between two firms’ managers, and he also considers managers colluding against their principals. A key difference between this paper and ours is that collusion is not sustained through relational contracting and only occurs when side payments are costless. As a result, allowing cross-firm managerial rewards always benefits the principals.

4See Banerjee, Mullainathan and Hanna (2013) for a survey of the corruption literature. Olsen and Torsvik (1998) find that potential supervisor-agent collusion can mitigate a commitment problem, but their model differs from ours by studying adverse selection rather than moral hazard. Most models of corruption abstract from enforcement problems; Martimort (1999) and Martimort and Verdier (2004) are notable exceptions, but they do not consider how
Our model also relates to a literature investigating how delegation to an intermediary can solve commitment problems.\textsuperscript{5} Within this literature, the paper closest to ours is that of Strausz (1997). He considers how delegating monitoring to an intermediary may benefit the principal through a ‘commitment effect’ and then studies the impact of collusion. The model differs from ours in a number of ways. For instance, he assumes that collusion is automatically enforced and that the supervisor can only trigger bonuses when the agent performs the (binary) action well. Given these different assumptions, he finds that potential supervisor-agent collusion has no impact on the principal’s payoff, contrary to our results.

1 Examples of ‘dual’ relational contracts

We begin by motivating our investigation with examples of two types of relationship that frequently sustain both productive and corrupt implicit contracting: relationships between firms delegated to purchasing managers and firm-employee relationships delegated to supervisors. We document evidence on how the two parts of these relational contracts may interact and demonstrate the existence of trade-offs that result.

1.1 Procurement and relationships between firms

It is now well established that relational contracts play a key role in transactions between organizations, including inter-firm trade and public procurement. A typical example is the purchase of goods where it is difficult to observe quality before buying. In this case, the purchaser may rely on a relational contract, inducing the seller to produce high quality by threatening partial nonpayment or the termination of the relationship.

Many procurement relationships are delegated to intermediaries, and it is well known that such delegation carries risks of kickbacks or other corrupt behavior. A typical example is a purchasing manager who has discretion regarding

\textsuperscript{5}Earlier papers in this literature include Vickers (1985), Katz (1991), and Kockesen and Ok (2004). Like much of this literature, we assume that the intermediary’s payoff function is observed by the agent. Our results may, however, be less vulnerable to principal-supervisor renegotiation than those of other papers, since in our context part of the supervisor’s payoff comes directly from the agent - see Section 5.2.1 for more details.
prices paid to suppliers. A study of Indian firm-owners by Bloom et al. (2013, p. 40) notes that many “did not trust non-family members. For example, they were concerned if they let their plant managers procure yarn they may do so at inflated rates from friends and receive kickbacks”. Indeed, Lambsdorff and Teksöz (2005, p. 139) argue that delegating responsibility for relational contracts is particularly vulnerable to corruption because “pre-existing legal relationships can lower transaction costs and serve as a basis for the enforcement of corrupt arrangements”.

Cole and Tran (2011) give evidence that these two aspects of relational contracts are interlinked. They describe kickbacks made by two firms to intermediaries within organizations that they supply. In one case, they note that relational contracts are needed because quality is not contractible and hence “the supplier allows the client to hold back roughly 20 percent of the contract value until ... the client is satisfied that the product meets the specified quality. The kickback is paid only after all contract payments have been made.” (p. 411). In another case, the agent “usually specifies the kickback amount in advance but typically does not start paying until the first deposit is made” (p. 420). In both cases the ordering of payments suggests that kickbacks are partly being used as an enforcement device to enhance the intermediary’s credibility.

1.2 Labor relations and organizational structure

A large portion of the relational contracting literature has focused on labor relations within organizations. Employees are frequently rewarded for effort with promotions, wage increases, or bonuses based on unverifiable subjective performance evaluations rather than contracted measures of output.

In many organizations these relational contracts are delegated to intermediary managers who have substantial control over incentives. The risk of collusion between intermediaries and employees in this setting is well known; Milgrom (1988), Fairburn and Malcomson (2001), and Thiele (2013), for instance, each consider the possibility of employees engaging in wasteful collusion or ‘influence activities’. As an example, Nkamleu and Kamgnia (2014) document that

---

6Similarly, Bloom, Sadun and Van Reenen (2012, p. 1667) find multinationals decentralize less in low-trust environments, and argue that CEOs “worry about the plant manager taking bribes from equipment sellers”.

7These papers implicitly assume that such manager-employee collusion can be automatically
in African governments per-diems are “mainly given to provide financial incentives to employees in order to increase their motivation” (p. 4) but managers may “expect the staff member to share or kickback a portion of the per diem” (p. 12). Indeed, Rasul and Rogger (2016) find evidence in Nigeria that influence activities lead subjective performance evaluations to damage production.

The dual nature of relational contracts within organizations leads to conflicting implications regarding their value. For instance, Francois and Roberts (2003) argue that factors enabling relational contracts within firms increase employee productivity and innovation. On the other hand, Martimort and Verdier (2004) argue that the same factors increase the ability of supervisors and employees to collude and hence dampen economic growth. Clearly both interpretations are possible, but it is difficult to evaluate the potential trade-off without understanding how the two parts of the relational contract interact.

2 The model

There are three players in our model: a principal, a supervisor, and an agent. We refer to the principal and supervisor as female and the agent as male. The model is similar to a standard one of principal-agent contracting, such as Levin (2003), except that the principal delegates responsibility for managing the contract to the supervisor. In particular, the principal sets three key parameters at the beginning of the game, but then takes no further action.

The three parameters set by the principal are the wage $w$ that the agent receives, a cap $b$ on the size of the bonus that the supervisor can disperse, and a proportion $\alpha$ of profit that is given to the supervisor. These parameters apply for each period and cannot vary over time or as a function of output. After these parameters are set, the supervisor and agent interact repeatedly over an infinite horizon of discrete periods.

enforced, and hence do not explore how this behavior relates to relational contracts. Thiele (2013) considers a principal who may operate a relational contract with the agent, but assumes that delegation to a corruptible supervisor results in all contracts becoming court-enforceable.

Section 5.2.3 considers the possibility of allowing the wage to vary over time. Another way in which the principal could improve her payoff would be to replace the bonus cap with some sort of cap on ‘average’ bonuses. In practice, however, such a restriction may be too complex and subject to renegotiation, since the principal would like to ‘reset’ the bonus cap after several periods of high output.
The timeline for each period is given in Figure 1. The supervisor first proposes a compensation package and a set of side payments to the agent. The agent either accepts or rejects - let $d_t \in \{0, 1\}$ denote the agent’s decision. If the agent rejects, then the principal, supervisor, and agent get their outside options $(1 - \alpha)\bar{\pi}, \alpha\bar{\pi},$ and $u$. If the agent accepts, then he chooses an effort $e_t \in [0, 1]$ incurring a cost $c(e_t)$, where $c(0) = 0$, $c'(0) = 0$ and $c''(\cdot) > 0$. The agent’s effort generates a binary stochastic output $Y_t \in \{0, y\}$ where $0 < y$. The output is high ($Y_t = y$) with probability $e_t$ and low ($Y_t = 0$) otherwise.

![Figure 1: Timeline of period t in supervisor-agent game](image)

The agent’s compensation package consists of the fixed payment $w$ and a noncontractible payment $b_t \in [0, \bar{b}]$ that can depend on output $Y_t$; let $W_t = w + b_t$ denote the total payment made. In the context of procurement relationships, we can think of $w$ as the upfront payment and $b_t$ as the payment made after inspection of quality $Y_t$.

In addition to the compensation package, the supervisor also suggests a package of side payments that will be made from the agent to the supervisor. The kickback is paid in two parts: the first part, $s^F_t$, is paid before output is realized, while the second part, $s_t$, is paid after output is realized. Let $S_t = s^F_t + s_t$ denote the total side payment made.

The information structure is one of moral hazard. Effort is the agent’s private

---

9The assumption that outside options are shared in the same proportion as profits ensures our results are not driven by different relative valuations of the outside option.

10We assume that bonus payments $b_t$ can be anywhere within the range $[0, \bar{b}]$, but it would not change our results if the supervisor could only choose between $b_t = 0$ and $b_t = \bar{b}$. In this case, mixed strategies would allow her to promise intermediate values in expectation.
information, while the output and agent’s compensation are observed by both the supervisor and the agent.\footnote{Since we assume that the principal has no actions after the beginning of the game, what she observes is irrelevant. In reality, not observing output and side payments may partly explain non-intervention.}

The profit $Y_t - W_t$ is split between the principal and supervisor, who receive shares $1 - \alpha$ and $\alpha$, where $\alpha \in [0, 1]$. All players have the same discount factor $\delta \in (0, 1)$. The payoff functions are given as follows:

\[
\pi_t = E \left[ (1 - \delta) \sum_{\tau=t}^{\infty} \delta^{\tau-t} \{ d_\tau [(1 - \alpha)(Y_\tau - W_\tau)] + (1 - d_\tau) (1 - \alpha)\pi \} \right]
\]

\[
u_t = E \left[ (1 - \delta) \sum_{\tau=t}^{\infty} \delta^{\tau-t} \{ d_\tau [\alpha(Y_\tau - W_\tau) + S_\tau] + (1 - d_\tau) \alpha\pi \} \right]
\]

\[
u_t = E \left[ (1 - \delta) \sum_{\tau=t}^{\infty} \delta^{\tau-t} \{ d_\tau [W_\tau - S_\tau - c(e_\tau)] + (1 - d_\tau) \mu \} \right]
\]

We define $g_t$ to be the surplus generated in the relationship between the supervisor and the agent, i.e. $g_t = \nu_t + u_t - \alpha\pi - \mu$.

A key assumption in the model is that the supervisor receives a fraction $\alpha$ of the profit $Y_t - W_t$.\footnote{We choose this form of supervisor payoff as it is the simplest that generates the key insights of the paper. Section 5.2 discusses alternatives, including where the supervisor receives a wage directly and has different weights on $W_t$ and $Y_t$, and shows that the main results still hold.} One way of squaring this with the assumption that neither the principal nor the supervisor can contract with the agent on $Y_t$ is to consider a situation where there are many identical agents. Each agent produces an output $y_{it}$ that is noncontractible, but the collective output $Y_t = \sum_i y_{it}$ is contractible. As the number of agents becomes large, the principal will do better by delegating to a supervisor who oversees all of them than by contracting with each agent on the collective output.\footnote{We omit a formal proof here, but a closely related result is proven by Rayo (2007). He studies repeated moral hazard with multiple agents when it is possible to contract explicitly on aggregate output and implicitly on individual output. He shows that, under certain conditions, it is optimal for the effective principal to contract relationally with the agents rather than use explicit contracting.}
3 Optimal supervisor-agent contracts

In this section we temporarily setting aside the actions of the principal and consider how the supervisor and agent interact for any given parameters $w$, $\bar{b}$ and $\alpha$. This is useful as a first step in understanding the principal’s optimal behavior and also provides insights for contexts where principals may not be optimizing over these variables. Optimal strategies for the principal are then considered in Section 4.

We begin this section by considering the benchmark case when $\alpha = 1$, since this is equivalent to a standard principal-agent model. We then consider the more general case when $\alpha < 1$ and solve for the optimal supervisor-agent contracts.

3.1 Optimal supervisor-agent contracts when $\alpha = 1$

If $\alpha = 1$, then our model is equivalent to one of principal-agent relational contracting such as Levin (2003). Side payments, bonuses, and wages are substitutable tools for making transfers between the two players. The cap on bonuses and the invariance of wages have no consequence because side payments are a perfect substitute. Moreover, the supervisor receives all of the profit and hence has the same payoff function as the principal would without delegation. We can thus treat the results of this case as the ‘no delegation’ benchmark and refer to them as the outcome of direct principal-agent relational contracting.

If the supervisor and agent could contract explicitly on $Y_t$, it would be optimal to induce the value of effort $e_t$ that maximizes the joint surplus, $y e_t - c(e_t)$. Defining this first-best effort as $e^{FB}$, we then have $c'(e^{FB}) = y$.

When the supervisor and agent cannot explicitly contract on $Y_t$, a self-enforcing contract is needed. We follow the definition of a self-enforcing contract given by Levin (2003) and similarly define a self-enforcing contract as optimal if no other self-enforcing contract generates higher expected surplus for the supervisor and agent. Levin (2003) shows that, if we are concerned with optimal contracts, then there is no loss of generality in focusing on stationary optimal contracts. Moreover, any optimal contract will have effort constrained by the following inequality:

$$c'(e) \leq \frac{\delta}{1 - \delta}(ey - c(e) - \pi - u)$$

(1)
Note that the right hand side of the this inequality is the discounted joint surplus generated by the supervisor-agent relationship. When the future relationship is not valuable enough, the supervisor cannot credibly pay a bonus large enough to implement the first-best effort. Instead, the effective reward for high output will be the largest that can be credibly promised. Effort will therefore be increasing in the discounted joint surplus.

3.2 Optimal supervisor-agent contracts when $\alpha < 1$

In this section, we first show that we can still restrict our attention to stationary contracts that maximize joint supervisor-agent surplus. We then outline the key constraints that will potentially bind in any optimal supervisor-agent contract. This allows us to derive the main proposition in this section, which characterizes the optimal contract as a function of the discounted joint surplus. Finally, we examine the varying ways in which effort is motivated and detail how the relationship between effort and surplus is nonmonotonic.

A first point to note is that, when $\alpha < 1$, the surplus generated directly depends on the compensation scheme. This is because the supervisor only pays for part of the payment $W_t$ that the agent receives. If explicit contracting on $Y_t$ were possible, the supervisor and agent would maximize their joint surplus by setting bonuses at the bonus cap $\bar{b}$ regardless of output and inducing an effort level $e_{SA}^{FB}$, where $c'(e_{SA}^{FB}) = \alpha y$.

Side payments can be used to divide surplus between the supervisor and agent. We can therefore focus on relational contracts that generate the largest possible supervisor-agent surplus. We follow Levin (2003) in defining a self-enforcing contract as strongly optimal if the continuation contract is optimal for all potential histories, even those off-equilibrium.\footnote{The concept of strong optimality defined by Levin (2003) is an equilibrium selection device that implicitly assumes that renegotiation can only take place if there are potential Pareto improvements; see Goldlücke and Kranz (2013) for how this condition relates to other renegotiation-proof concepts. Miller and Watson (2013) construct an alternative condition that assumes players bargain within each period and show that this typically involves suboptimal play after deviation.} We then obtain the following lemma:

**Lemma 1.** If an optimal contract exists, there are stationary contracts that are strongly optimal.
The intuition behind this stationarity result is that any variation in promised continuation values can be transferred into side payments in the same way that, in the principal-agent case studied by Levin (2003), any variation can be transferred to bonus payments.

We therefore focus on stationary contracts and drop the $t$ subscripts on our variables. Let $b_h$ be the bonus when output is high ($Y = y$), $b_l$ that when output is low ($Y = 0$), and define $s_h$ and $s_l$ similarly. Then effort will be determined by the following binding incentive compatibility constraint:

$$c'(e) = b_h - b_l - s_h + s_l \quad (IC)$$

We define $g(e, b_h, b_l)$ as the expected supervisor-agent surplus in any stationary contract that has bonuses $b_h$ and $b_l$ and induces effort $e$. This is given by the following equation:

$$g(e, b_h, b_l) = \alpha ey + (1 - \alpha)(w + eb_h + (1 - e)b_l) - c(e) - u - \alpha \pi$$

Note that, within stationary contracts, there are two ways that the supervisor can motivate effort: through variation in bonuses or in bribes. The following lemma shows that bonuses will never be negative and, if bribes or bonuses vary as a function of output, then they will do so in a way that encourages effort.

**Lemma 2.** In any optimal contract, bonuses are always nonnegative, i.e. $b_h \geq 0$ and $b_l \geq 0$. Moreover, bonuses are weakly higher when output is high ($b_h \geq b_l$) and side payments are weakly lower ($s_h \leq s_l$).

If the supervisor wants to take surplus from the agent, then she prefers to do so using bribes rather than bonuses. This is because bribes and bonuses are equivalent for the agent, but the supervisor captures the whole value of any bribes given.

The need for the contract to be self-enforcing can be expressed in terms of dynamic enforcement constraints which demand that the future benefits of continuing the relationship are larger than the static gains from reneging on promises. Lemma 2 pins down the binding dynamic enforcement constraints that potentially bind. Since bonuses are never negative, only the supervisor has a reason to deviate when it comes to the bonus payment. This temptation will be greatest when output is high, as this is when the bonus is greatest. On the
other hand, only the agent may wish to deviate from paying the agreed side payments, because if the supervisor does not wish to pay the side payment, she already would have deviated by not paying the bonus. The agent will be most tempted to renege when output is low, as this is when the side payment is greatest. We therefore need to concentrate on the two following dynamic enforcement constraints:

\[(1 - \delta)(-\alpha b_h + s_h) + \delta u \geq \delta \alpha \pi \]  
\[-(1 - \delta)s_l + \delta u \geq \delta u \]

\[(DE_S) \quad \quad (DE_A)\]

From these constraints, we can see that variation in bonuses is easier to sustain than variation in bribes. Increasing \(b_h\) by 1 only tightens \((DE_S)\) by an amount \(\alpha\), but increasing \(s_l\) or decreasing \(s_h\) by 1 tightens the constrains by 1. In other words, motivating effort through bonuses is easier than motivating effort through bribes.

Summing \((DE_S)\) and \((DE_A)\) together and substituting in \((IC)\) then gives us the following constraint:

\[c'(e) + \alpha b_h - [b_h - b_l] \leq \frac{\delta g(e, b_h, b_l)}{1 - \delta} \]

\[(IC - DE)\]

Comparing this to (1), the equivalent in the principal-agent case, we see that the requirement for contracts to be self-enforcing has a more complex impact in the supervisor-agent game. In particular, as the surplus in the relationship decreases, a reduction in effort is now only one possible effect. The supervisor and agent may instead choose to keep effort constant and increase the difference in the bonuses. This makes relational contracting easier since it is more credible for the supervisor to induce effort using bonuses rather than bribes.

Define \(\delta^{FB}\) as the critical level of \(\delta\) at which the supervisor and agent can implement their first-best contract, i.e.

\[\frac{\delta^{FB}}{1 - \delta^{FB}} = \frac{\alpha y + \alpha \tilde{b}}{g(e^{FB}_{SA}, b_h, b_l)}\]

Then we obtain the following lemma:

**Lemma 3.** If \(\delta \leq \delta^{FB}\), then \((IC - DE)\) is binding.

The ability to transfer utility through side payments ensures that there cannot be a second-best optimal contract where one of the dynamic enforcement constraints has slack. Hence, in any optimal contract that does not achieve first best, both \((DE_S)\) and \((DE_A)\) will be binding, and therefore so will \((IC - DE)\).
From \((IC - DE)\), we can see that changes in discounted surplus may affect effort, the bonus \(b_h\), and the extent to which effort is induced through variation in bonuses rather than bribes. The following proposition characterizes the optimal contract as a function of \(\delta\) and shows that the relationship between effort and \(\delta\) is nonmonotonic. We can think of \(\delta\) as a determinant of the potential discounted joint surplus, and indeed the proposition could be written similarly in terms of the wage \(w\) or the outside options \(\pi\) and \(u\).

**Proposition 1.** Effort may be a nonmonotonic function of the surplus. In particular, there exist values \(\delta^L\) and \(\delta^H\) such that the optimal supervisor-agent relational contract can be characterized as follows:

- **High surplus:** If \(\delta \geq \delta^H\), then bonuses are not used to induce effort, i.e. \(b_h = b_l\), and effort is weakly increasing in \(\delta\).

- **Intermediate surplus:** If \(\delta^H > \delta > \delta^L\), then both bribes and bonuses are used to induce effort, i.e. \(b_l < b_h\) and \(s_h < s_l\), and bonuses are at the cap when output is high, i.e. \(b_h = \bar{b}\). If \(b_l > 0\), then effort is decreasing in \(\delta\), and otherwise it is increasing in \(\delta\).

- **Low surplus:** If \(\delta \leq \delta^L\) then bribes are not used to induce effort, i.e. \(s_h = s_l\), and effort is weakly increasing in \(\delta\).

The basic intuition behind the nonmonotonicity result can be understood as follows. When surplus is high, the relationship can sustain both large unvarying bonuses and a large variation in bribes to induce effort. When surplus falls below a certain level, the supervisor replaces some of the variation in bribes with variation in bonuses, since these are easier to sustain. Doing so means that effort benefits the supervisor and agent more, since high output now triggers higher bonuses. Lower surplus makes inducing effort more difficult, but this is more than compensated for by the increase in the value of effort for the two parties.

In order to better understand the nature of the optimal supervisor-agent contract, we now briefly detail the three cases outlined in Proposition 1. We also depict in Figure 2 the optimal contract for particular parameter values when \(c(e) = \frac{1}{2}ce^2\) and the supervisor and agent have equal bargaining powers, i.e. \(u = v = g/2\). Figures 2a and 2b plot the bonuses and kickbacks as a function
of $\delta$, with the latter including the expected bribe $s^F + es_h + (1 - e)s_l$. Figure 2c then plots the induced effort levels, and for comparison we also include the effort level that would be exerted without delegation. Finally, Figure 2d plots the players’ payoffs and the supervisor-agent surplus $g$.

Figure 2: Optimal supervisor-agent contract as a function of the discount factor

(a) Bonuses

(b) Bribes

(c) Effort

(d) Payoffs

$\bar{b} = 0.4$, $y = 0.9$, $c = 1.08$, $\alpha = 0.6$, and $w = 0.05$
3.2.1 High surplus

When surplus is slightly below the level that allows the supervisor and agent’s first-best contract, effort will be below first best but bonuses will remain at the cap regardless of output. In particular, since \((IC - DE)\) is binding, effort will be determined by the equation \(c'(e) = \frac{\delta g(e, b, b)}{1 - \delta} - \alpha \bar{b}\). Effort is reduced before bonuses because, when \(e = e_{SA}^{FB}\), a marginal reduction in effort leads to a second-order reduction in supervisor-agent surplus, while the cost of reducing the bonuses is first-order. There will thus always be a range of surplus for which the optimal contract involves \(b_l = b_h = \bar{b}\) and \(e < e_{SA}^{FB}\). Hence \(\delta^H < \delta^{FB}\).

When surplus falls further, what happens depends on the relative value that the supervisor places on output, \(\alpha\). If \(\alpha\) is low, then she will continue to cut effort rather than bonuses until no effort is sustainable. In this case \(\delta^H \leq \delta^L\) and there is no ‘intermediate’ range of surplus. If \(\alpha\) is high, then \(\delta^H > \delta^L\), and there will be an intermediate surplus range where bonuses are used to induce effort.

3.2.2 Intermediate surplus

The players face a trade-off when deciding upon the bonus given when output is low, \(b_l\). A higher \(b_l\) generates greater surplus directly, but it also decreases effort. Maximizing joint surplus gives us the following expression for \(b_l\) when \(\bar{b} > b_l > 0\):

\[
\frac{1 - \alpha}{\alpha} (1 - e) c''(e) - y + \frac{1}{\alpha} \frac{\delta g(e, b_h, b_l)}{1 - \delta}
\]

The first term of this expression stems from the direct gain in supervisor-agent surplus that an increase in \(b_l\) produces; the more likely low output is to occur, the higher this gain. The second term is the result of the reduction in expected output that an increase in \(b_l\) produces through the change in effort induced. The third term comes from the relational contracting constraint; higher surplus means that more effort can be induced through bribes, and hence \(b_l\) can be higher.

Since \((IC - DE)\) is binding, the effort level \(e\) is given by \(c'(e) = \bar{b} - b_l + \frac{\delta g(e, b, b_h)}{1 - \delta} - \alpha \bar{b}\). If we substitute in (2), we can see that effort is weakly decreasing in the discounted surplus if and only if \(b_l > 0\). When \(b_l > 0\), a decrease in the discounted surplus decreases \(b_l\) and hence the agent and supervisor have a
greater incentive to increase effort. Instead, when \( b_l = 0 \), a lower surplus forces
the supervisor to reduce the variation in bribes.

### 3.2.3 Low surplus

When the discounted surplus becomes low, i.e. \( \delta = \delta^L \), the supervisor can
only just promise to pay \( b_h = \bar{b} \) and will not be able to combine this with any
variation in bribes. When \( \delta \leq \delta^L \), the bonus \( b_h \) will be the maximum that the
supervisor can credibly promise, i.e. \( b_h = \frac{\delta \sigma(e, b_h, b_l)}{1 - \delta} \), and \( b_l \) will again be
either equal to \( b_h \), zero or a solution to (2).

### 3.3 Discussion

An important implication of Proposition 1 is that there is sometimes, but not
always, a trade-off between increasing production and reducing the surplus captured
by intermediaries. The previous literature on relational contracts suggests
that noncontractible production can be improved by increasing the discounted
joint-surplus within relationships, for instance by increasing tenure or decreasing
competitive pressure (Board, 2011; Gibbons and Henderson, 2013). Yet
those concerned with corruption argue that such policies will facilitate kickbacks (Martimort, 1999; Lambsdorff and Teksoz, 2005). Our analysis implies
that in some cases both effects may indeed occur simultaneously, and here the desirability of such policies will depend on weighing up both sides of this trade-off. In other cases, however, we find that there is no such trade-off, and in-
creasing surplus will both facilitate corruption and decrease production. In our
model, this corresponds to situations where the supervisor is on occasion dis-
pening the maximum possible bonus, but is never dispensing the minimum.

### 4 Optimal delegation for the principal

In the previous section, we ignored the role of the principal and treated the pa-
rameters \( w, \alpha \) and \( \bar{b} \) as exogenous. In this section, we consider that the principal
sets these parameters at the beginning of the game. We first solve for the optimal
parameters and describe the resulting contract. We then examine when the prin-
cipal will prefer to delegate rather than undertake direct relational contracting.
4.1 How should the principal delegate?

We begin by writing the principal’s payoff under delegation as a function of the supervisor-agent surplus $g$. Since the supervisor-agent contract will be stationary, we can write the principal’s payoff as follows:

$$\pi = ey - c(e) - g - u - a\pi$$

The principal effectively only cares about effort and the surplus given to the supervisor and agent; holding these constant, she is indifferent to the various potential compensation schemes. Furthermore, note from the definition of $g$ that, when $\alpha < 1$, the principal can set $g$ through the wage $w$.

The following proposition describes how the principal sets the parameters $w$, $\alpha$ and $b$ to maximize their payoff. The principal sets supervisor-agent surplus such that the contract is of the ‘low surplus’ type described in Proposition 1. Moreover, she chooses $\alpha$ such that the supervisor’s preferences are partly, but not entirely, aligned with her own, resulting in a contract with $b_h = \bar{b}$ and $b_l = 0$.

**Proposition 2.** The supervisor-agent contract under optimal delegation will only use bonuses to induce effort; bonuses will be zero when output is low and at the cap when output is high. If the optimal delegated contract involves positive effort, then the optimal value of $\alpha$ for the principal lies strictly between 0 and 1.

The intuition behind the first part is that inducing effort through variation in bribes requires greater supervisor-agent surplus than using bonuses. The principal therefore prefers effort being induced using bonuses since it involves giving up less surplus. The principal can always improve on any contract that has variation in bribes by increasing the bonus cap and decreasing the wage in order to induce the same level of effort entirely through bonuses.

When it comes to setting $\alpha$, the principal faces a trade-off. On the one hand, she wishes to decrease $\alpha$ in order to facilitate supervisor-agent relational contracting; easier relational contracting reduces the amount of surplus the principal needs to give to the supervisor and agent. On the other hand, she needs to ensure that $\alpha$ is sufficiently high that the optimal supervisor-agent contract involves no bonuses when output is low, i.e. $b_l = 0$. A contract with $b_l > 0$ is not optimal since the principal could lower the bonus cap $\bar{b}$ and the wage $w$ in order to
induce a contract with the same variation in bonuses but with $b_l = 0$.

If the optimal contract involves positive effort, it must have $\alpha > 0$. Otherwise, if $\alpha = 0$, then the supervisor and agent will strictly prefer a contract that induces no effort, since effort is costly and brings them no rewards.

To see why the optimal contract has $\alpha < 1$, note that we have $s_l = s_h$ and $b_l = 0$, and hence $c'(e) = b_h = \frac{1}{a} \frac{\delta g}{1 - \delta}$. The principal will therefore be maximizing the following expression:

$$
\pi = ey - c(e) - \alpha \frac{1 - \delta}{\delta} c'(e) - \alpha \pi - u
$$

(3)

Since this expression is decreasing in $\alpha$, the principal will set $\alpha$ at the lowest level at which it is possible to induce a contract with $b_l = 0$ and effort at the desired level. Since this must involve $\alpha > 0$, (3) tells us that the optimal effort induced will be below $e^{FB}$. The principal must set $\alpha$ such that the supervisor and agent will prefer to induce effort rather than set $b_l = b_h$, which requires $\alpha \geq \frac{(1 - e) c'(e) + e(e)}{(1 - e) c'(e) + ye}$. She must also ensure that $b_l = 0$ is chosen rather than a level $0 < b_l < b_h$, but from (2) we will have no such interior solutions so long as $\alpha \geq \frac{(1 - e)c''(e)}{(1 - e)c'(e) + ye}$. Examining both of these requirements we can see that, when $e < e^{FB}$, the principal can set $\alpha < 1$. In other words, since the principal does not want to induce first-best effort, she does not require a supervisor who fully internalizes the benefits of effort.

**4.2 When should the principal delegate?**

The previous section considered the optimal way for the principal to delegate a relational contract to a supervisor. In some situations, delegation may be obliged; the leader of a government or large firm may simply be unable to manage all relevant relational contracts themselves. In other situations, the principal may have the choice between delegating the relational contract to a supervisor or managing it herself. In this section, we consider when such delegation may be in the principal’s best interest.

The following proposition describes when the principal should delegate, assuming she does so optimally. If she does not delegate, we assume she undertakes direct relational contracting with the agent, achieving the results outlined in Section 3.1. The proposition states that there exists a range of discount fac-
tors for which delegating is strictly preferable and a higher range when direct relational contracting is strictly preferable.

**Proposition 3.** There exist values $\hat{\delta}, \tilde{\delta}$ and $\overline{\delta}$ with $0 \leq \hat{\delta} < \tilde{\delta} \leq \overline{\delta} < 1$ such that:

- If $\hat{\delta} > \delta > \tilde{\delta}$, then the principal’s payoff from optimally delegating is strictly below that from direct relational contracting.

- If $\hat{\delta} > \delta > \tilde{\delta}$, then the principal’s payoff from optimally delegating is strictly above that from direct relational contracting.

If the discount factor is high, then relational contracting poses no problem, and there is no reason to delegate. The principal and agent can implement first-best effort on their own, and the principal has no reason to share surplus with the supervisor. On the other hand, if the discount factor is low, then direct relational contracting is difficult and cannot sustain much effort. The principal would therefore prefer to delegate and thus generate more effort, since the extra surplus generated more than compensates for the part given to the supervisor.

Figure 3: Principal’s payoffs with and without delegation

(a) Discount factor, $\delta$

(b) Agent’s outside option, $u$

\[ y = 0.9, \ c = 1.08 \text{ and } \pi = 0. \text{ When not plotted, } \delta = 0.55 \text{ and } u = 0. \]

A similar logic applies for other variables affecting the potential discounted surplus, including the agent’s outside option $u$. Figure 3 demonstrates these results graphically by plotting the best payoffs that the principal can achieve with and without delegation when $c(e) = \frac{ce^2}{2}$. In this case we have a single crossing point in the payoffs, i.e. $\hat{\delta} = \overline{\delta}$, but this will not necessarily be the case for other functional forms.
4.3 Discussion

Proposition 2 tells us that the principal would like a supervisor whose payoffs are partly, but not completely, aligned with her own. The principal needs the supervisor to care somewhat about profit because otherwise no effort will be induced. This makes supervisor-agent relational contracting costly, which means that to get more effort the principal has to give up more surplus. As a result, the principal will not wish to induce first-best effort when delegating, and hence there is no need to have a supervisor whose incentives align completely with her own. Instead, the principal would rather have a supervisor who cared less about profit in order to facilitate relational contracting. If the supervisor is motivated in this way, Proposition 3 then states that delegating can be beneficial for the principal when she has difficulty committing, but not otherwise.

An example of such behavior can perhaps be seen in the way in which Chinese firms deal with the practice of Guanxi, a system of informal relationships often formulated through gift exchange. Firms are well aware of the risks stemming from procurement and sales managers’ personal relationships, since these can facilitate kickbacks and other malpractice (Millington, Eberhardt and Wilkinson, 2005). Yet, when it comes to hiring such personnel, Wiegel and Bamford (2015) find evidence that firms specifically hire people with personal Guanxi, and they cite the ability of Guanxi to smooth inter-firm relationships as an important factor. Indeed, Schramm and Taube (2003) argue that whilst Guanxi networks facilitate corruption, this corruption itself helps to strengthen the legitimate transactions coordinated through Guanxi, in a way similar to that described in our model above.

5 Alternative specifications and extensions

In this section we consider a number of alternative ways in which we could set up our model and discuss how this would affect our results. We begin by considering how the principal would behave if $\alpha$ was exogenous, and then examine cases where she has more instruments at her disposal. Finally, we briefly sketch how the results would change were there to be a cost to side payments.
5.1 Exogenous $\alpha$

The assumption that $\alpha$ is chosen by the principal may be reasonable in contexts where the principal designs the supervisor’s contract, but unreasonable in others. For instance, Chassang and Padró i Miquel (2014) argue that payoff functions are rarely available as policy instruments in settings with corruption. An important situation where $\alpha$ may be exogenous is when it represents the supervisor’s intrinsic motivations.

When $\alpha$ is high, the principal will induce an optimal ‘low surplus’ contract as described in Proposition 2. When $\alpha$ is low, however, such a contract cannot generate much effort, since the supervisor and agent would rather pay high bonuses when output is low than use bonuses to induce effort. In this case, the principal is better off allowing the supervisor no discretion (i.e. $\bar{b} = 0$) and delegation will decrease the principal’s payoff. This is consistent with the results of Rasul and Rogger (2016), who find that subjective performance evaluation produces better results when supervisors are more intrinsically motivated.

5.2 Additional instruments for the principal

Proposition 2 showed that, under optimal delegation, bribes will occur and effort will be below the level that maximizes total surplus, $e^{FB}$. It is natural to ask whether these results would change if the principal had more instruments at her disposal. We therefore now consider the introduction of three new instruments: a wage for the supervisor, an initial transfer to the principal, and the ability to share output and costs by different proportions.

5.2.1 A wage for the supervisor

In the model we have used, only the agent receives a wage from the principal. Corruption therefore plays an important role by allowing the supervisor and agent to split the surplus. Were the principal able to pay a wage to the supervisor, wages could be tailored so that the optimal contract involved no bribes in equilibrium. Delegation can therefore benefit the principal without corruption if instead the supervisor receives regular payments that are conditional on the relationship being maintained. Allowing for such a wage will not change any of the propositions above, since the principal would be indifferent between paying
the supervisor directly and paying her through corruption.

One reason why delegated relational contracts may be sustained by side payments rather than payments from the principal is that the principal has limited information. To induce an optimal contract without corruption, the principal needs to know the relative bargaining powers of the supervisor and agent. Moreover, Hermalin (2015) argues that the principal may imperfectly observe when the intermediary is cooperating. If the supervisor might continue to receive payments from the principal after termination, then payments would also increase the supervisor’s outside option. For this reason, side-payments may be a more effective tool for sustaining delegated relational contracts.

The principal may also rule out direct transfers to the supervisor to reduce the potential for future renegotiations. Katz (1991) and Kockesen and Ok (2004) show that if unobservable renegotiation is possible, then delegation loses much of its ability to solve commitment problems. Hence delegated relational contracting sustained by side payments may be more credible than delegation with relatively flexible principal-supervisor transfers.

5.2.2 A more general sharing rule

We previously assumed that the supervisor receives a share $\alpha$ of the profit. A more general contract would place a different weight on output to that placed on bonuses. For instance, consider the following payoff function for the supervisor:

$$v_t = (1 - \delta)E \left[ \sum_{\tau=t}^{\infty} \delta^{\tau-t} \left( d_{\tau} \left[ a_Y Y_{\tau} - a_b b_{\tau} + w_S + S_{\tau} \right] + (1 - d_{\tau}) a_{\bar{X}} \right) \right]$$

where $a_Y$ and $a_b$ are the weights placed on output and bonuses, and $w_S$ is a wage paid by the principal to the supervisor. We assume that $a_b \geq 0$ and $a_Y \leq 1$.

In this case, the nature of supervisor-agent optimal contracts do not change substantially, and Proposition 1 remains unchanged. For the principal, the optimal value of $a_Y$ is 1. This is because a higher $a_Y$ encourages the supervisor to induce more effort, and there is no cost to the principal in increasing $a_Y$ since she can extract surplus through wages.

\footnote{If the principal could set $a_Y > 1$, then she could achieve first best through delegation, but she would receive a negative share of profits each period. It is common in the literature to focus on nonnegative shares, as negative shares are difficult to implement in practice (Rayo, 2007).}
When it comes to setting $\alpha_b$ and $e$, the trade-offs are similar to before. Lowering $\alpha_b$ facilitates relational contracting, but it also makes the supervisor care less about inducing effort relative to increasing bonuses. The only way the principal can induce first-best effort is by setting $\alpha_b = 1$, but this is not optimal since at $e = e^{FB}$ the principal prefers lower effort in exchange for keeping more surplus. Hence she will set $\alpha_b < 1$ and induce an effort level $e < e^{FB}$. Note that it may be optimal for the principal to set $\alpha_b = 0$. This makes relational contracting between the supervisor and agent unnecessary because the supervisor has no temptation not to pay promised bonuses. In this case, the principal only needs to give the supervisor and agent their outside options.

5.2.3 Initial transfer to the principal

An important assumption in our model is that the wage $w$ is fixed over time. Hence, when setting the wage, the principal faces a trade-off; a higher wage costs the principal directly, but it also increases the supervisor-agent discounted surplus and hence allows for greater effort. If the wage was allowed to vary over time, however, the principal would face no such trade-off. Instead, she could set high future wages to ensure a large supervisor-agent discounted surplus and a very low, potentially negative, initial wage to extract this surplus ex ante.

In the extreme, allowing an initial fee to be paid to the principal by the supervisor or agent would allow the principal to achieve the first best. In particular, she could set $\alpha = 1$, extract all the surplus via an ex ante transfer, and then set future wages to be sufficiently large that the supervisor could credibly promise to pay bonuses of size $y$. But, if direct principal-agent relational contracting cannot also produce the first best, then achieving the first-best with delegation requires a wage larger than the total surplus generated each period. In some sense, therefore, the principal is improving her payoff not by delegation, but by being able to borrow in the first period and then invest in a financial product that only pays out if the relationship is sustained.

A realistic model allowing for initial transfers would therefore demand that wages (or total compensation) be capped at some level less than or equal to the period surplus. First-best effort would then only be achievable under delegation if it was achievable without delegation, since the supervisor will only be willing to induce $e^{FB}$ if $\alpha = 1$. Overall, therefore, allowing wages to vary over time in a
reasonable way will not result in first-best effort with delegation if the principal cannot achieve first best with direct relational contracting.

5.3 Costly corruption

We have assumed for simplicity that side payments between the supervisor and agent are costless except to the extent that they need to be self-enforced. In reality, however, side payments may be intrinsically costly. For instance, there may be a risk of punishment, and payments may be made in an inefficient way to avoid detection. A typical modeling assumption used to capture this is to assume that a side payment which costs the agent \( s \) only gives a benefit of \( \kappa s \) to the supervisor, where \( \kappa < 1 \). Adding such a parameter to our model would make it substantially more complex, but we can sketch two important changes that would result.\(^{16}\)

First, when considering optimal supervisor-agent contracts, we could no longer restrict our attention to stationary contracts. Since the supervisor could not extract the full value of future bonuses from the agent, she may instead use the promise of future bonuses to motivate effort.\(^{17}\)

Second, since the risk of corruption would be reduced, the principal could set a lower value of \( \alpha \) and still avoid \( b_l > 0 \). Indeed, if side payments were impossible (\( \kappa = 0 \)), then the principal could set \( \alpha = 0 \) and induce first-best effort. This would be a knife-edge result in the main model considered in this paper, since behavior would be very different with \( \kappa = \epsilon \) or \( \alpha = \epsilon \) for any \( \epsilon > 0 \). The result would not be knife-edged, however, if we allowed for the principal to pay the supervisor a direct wage or to split \( \alpha \) into \( \alpha_Y \) and \( \alpha_b \). Thus in general the principal would prefer for corruption to be more costly.

\(^{16}\)Our results thus contrast with Strausz (1997), who in an alternative model of delegation finds outcomes are the same whether or not supervisor-agent collusion is possible (i.e. \( \kappa = 1 \) or \( \kappa = 0 \)). We would obtain the same result if we made two changes to make our model closer to his. In particular, if we assumed that \( e_f = 1 \) and the principal could pay the supervisor conditional on output and bonuses, then she could set \( \alpha = 0 \), offer the supervisor a large payment in exchange for setting \( b_l = 0 \), and achieve the first-best with output always high.

\(^{17}\)Optimal supervisor-agent contracts would be similar to the relational contracts described in Fong and Li (2015), which can be seen as an example of the ‘backloading’ principal expounded by Ray (2002). One difference would be that, if the cost of corruption was sufficiently low, the supervisor would threaten the agent with having to pay a bribe rather than with termination.
6 Conclusions

This paper has studied the impact of delegating relational contracts to corruptible intermediaries, and in doing so has generated a number of empirical implications. On the one hand, we have seen that relationships that enable corruption may be the same as those that encourage valuable production. Hence the prevalence of corruption and kickbacks in contexts where explicit contract enforcement is weak may stem partly from the resulting reliance on relational contracting. Indeed, we have shown that principals may want their supervisors to be somewhat susceptible to corruption, and this may help to explain why politicians and firm owners frequently turn a blind eye to employees accepting kickbacks. On the other hand, we have also shown that corruption can crowd out productive effort if the relationship between supervisor and agent is too strong. Indeed, the risks of corruption may be sufficiently large that a principal would rather manage a relationship herself than delegate to an intermediary. Governments and firms therefore face a delicate balancing act when it comes to making a trade-off between productive relational contracts and corruption.

An important next step will be to test the results of this paper in empirical work. Side payments are difficult to measure, but it should be possible to test our results on other variables such as output, discretionary rewards and discounted surplus. We could, for instance, test directly for a nonmonotonic relationship between effort and surplus in contexts where there is a risk of corruption. Moreover, we may evaluate whether principals are behaving in a way consistent with this model by observing variation in delegation decisions. A potentially underexplored area may be investigating firm owners’ concerns with employee fraud in procurement, particularly in developing countries where explicit contracts are weak.

There are also multiple theoretical extensions to the model that would be valuable to pursue. For instance, we have assumed that the supervisor’s preferences are known, but in reality there is uncertainty as to ‘how corrupt’ any individual is. Removing this assumption, possibly in a similar way to Chassang (2010) or Chassang and Padró i Miquel (2014), may reveal insights into how corruption and effort evolve over time. We may also ask whether corrupt relational contracts make supervisors more likely to stick with the same firm over time. This may add an extra inefficiency, or help to enhance valuable loyalty.
Mathematical Appendix

Proof of Lemma 1. The proof is analogous that of Theorem 2 in Levin (2003), only we must define new side payments, rather than new bonus payments and wages, to produce the stationary contract. \(\square\)

Proof of Lemma 2. For the first part, consider an optimal contract with \(b_h < 0\). Then consider an alternative contract with bonus \(b'_h = 0\) and side payment \(s'_h = s_h - b_h\). It is simple to check that all the self-enforcing constraints are still satisfied. Moreover, this contract has a higher surplus, and therefore the original contract cannot be optimal. The same logic holds if \(b_l < 0\).

For the second part, first suppose that \(s_h > s_l\). Then, consider an alternative contract with \(s'_l = s_h\), \(b'_l = b_l + s_h - s_l\). This alternative contract must also be self-enforcing, yet surplus is greater. Hence the original contract is not optimal. In the case of bonuses, if \(b_h < b_l\), then we can similarly consider an alternative contract with \(b'_h = b_l\) and \(s'(y) = s_h + b_l - b_h\). \(\square\)

Proof of Lemma 3. First, consider an optimal contract with \((DE_A)\) not binding. If \(e < e^{FB}_{SA}\), then consider an alternative contract with \(s'_h = s_l + \epsilon\). This contract induces higher effort and, for some \(\epsilon > 0\), is self-enforcing. Thus we must have \(e \geq e^{FB}_{SA}\). If \(b_l < \bar{b}\), then consider a contract with \(b'_l = b_l + \epsilon\) and \(s'_l = s_l + \epsilon\). This contract generates higher surplus and, for some \(\epsilon > 0\), is self-enforcing. Thus we must have \(b_l = \bar{b}\). Lemma 2 then implies \(b_h = \bar{b}\).

Second, consider an optimal contract with \((DE_S)\) not binding. If \(e < e^{FB}_{SA}\), then consider an alternative contract with \(s'_h = s_h - \epsilon\). This contract generates higher effort and, for some \(\epsilon > 0\), will be self-enforcing. Hence we must have \(e \geq e^{FB}_{SA}\). If \(b_h < \bar{b}\), then we must have \(s_l = s_h\), since otherwise we can construct an alternative self-enforcing contract that generates higher surplus with \(b'_h = b_h + \epsilon\) and \(s'_h = s_h + \epsilon\), for some \(\epsilon > 0\). Since \(e > 0\), it therefore follows that \(b_l < b_h\), but now we can construct a self-enforcing contract with \(b'_h = b_h + \epsilon\) and \(b'_l = b_l + \epsilon\), for some \(\epsilon > 0\). Hence we must have \(b_h = \bar{b}\). Finally, if \(b_l < \bar{b}\), then we can consider a contract with \(b'_l = b_l + \epsilon\) and \(s'_l = s_h - \epsilon\) (since \(s_l \geq s_h\) from Lemma 2). But this contract is self-enforcing for some \(\epsilon > 0\) and has higher surplus. Hence we must have \(b_l = \bar{b}\).

Therefore, if either \((DE_A)\) or \((DE_S)\) is not binding, we must have \(b_h = \bar{b}\).
\( b_l = \overline{b} \) and \( e \geq e_{\text{SA}}^{FB} \). Summing \((DE_A)\) and \((DE_S)\) and substituting into \((IC)\) gives \(a\overline{b} + c'(e) < \frac{\delta}{1 - \delta} (v + u - a\overline{x} - u) \leq \frac{\delta g(e_{\Delta A}^{FB}, \overline{b}, \delta)}{1 - \delta}. \) But, since \( e \geq e_{\text{SA}}^{FB} \), we must have \( c'(e) \geq ay \), which implies \( \delta \geq \delta^{FB} \).

\[ \square \]

**Proof of Proposition 1.** If \( \delta \geq \delta^{FB} \), then the first-best contract is self-enforcing. This contract is ‘high surplus’ in the sense of the proposition. For the rest of the proof we consider the case when \( \delta < \delta^{FB} \). We first consider how the characteristics of the optimal contract change as a function of \( \delta \), and then how effort \( e \) changes as a function of \( \delta \) for each contract type.

First, note that both the surplus and effort level are increasing in \( b_h \), and hence \( b_h = \min\{\overline{b}, \frac{1}{a} \frac{\delta g^*_s}{1 - \delta}\}. \) From Lemma 3, \( \overline{b} \geq \frac{1}{a} \frac{\delta g^*_s}{1 - \delta} \), and hence we can define \( \delta^L \) such that \( \overline{b} = \frac{\delta^L g^*_s}{1 - \delta^L} \). There is a unique value of \( \delta \) that solves this equation since \( g^* \) is weakly increasing in \( \delta \). We now consider in turn the cases when \( \delta \geq \delta^L \) and \( \delta \leq \delta^L \).

If \( \delta \geq \delta^L \), then from Lemma 3 we have \( b_l = \frac{\delta g(e, \overline{b}, b_l)}{1 - \delta} + (1 - \alpha)\overline{b} - c'(e) \).

The supervisor and agent’s problem is to maximize the surplus function \( g_1(e) = g(e, \overline{b}, b_l) \) with respect to \( e \) subject to the boundary conditions on \( b_l \), i.e. \( 0 \leq b_l \leq \overline{b} \).

Differentiating this function with respect to \( e \) gives us:

\[ g'_1(e) = \frac{ay + (1 - \alpha)(a\overline{b} - (1 - \epsilon)c''(e)) - ac'(e) - \frac{\delta g_1(e)}{1 - \delta}}{1 - \delta - \delta(1 - \epsilon)(1 - \alpha)} \]

Let \( \overline{g}_1 \) and \( g_1 \) be the surpluses at the upper and lower boundaries and let \( \tilde{g}_1 \) be the surplus at the maximal interior solution. Define effort levels \( \overline{e}_1, e_1 \) and \( \tilde{e}_1 \) as the effort induced at these three potential solutions. Since we wish to characterize the optimal contract as a function of \( \delta \), we differentiate each of these surpluses with respect to \( \delta \), giving the following equations:

\[
\begin{align*}
\frac{d\overline{g}_1}{d\delta} &= \frac{\overline{g}_1}{1 - \delta} \frac{ay - c'(\overline{e}_1)}{1 - \delta(1 - \epsilon)c''(\overline{e}_1) - \delta(ay - c'(\overline{e}_1))} \\
\frac{d\tilde{g}_1}{d\delta} &= \frac{\tilde{g}_1}{1 - \delta} \frac{ay + (1 - \alpha)\overline{b} - c'(e_1)}{1 - \delta(1 - \epsilon)c''(e_1) - \delta(ay + (1 - \alpha)\overline{b} - c'(e_1))}
\end{align*}
\]
From (4), at any interior solution we have $c'(\tilde{e}_1) = y - \frac{1-a}{a} (1 - \tilde{e}_1) c''(\tilde{e}_1) - \frac{1-a}{a} \left( \frac{\delta \bar{g}_1}{1-\delta} - a\overline{b} \right)$. Thus, at any $\delta$ where $\bar{g}_1 = \tilde{g}_1$, we have we have $c'(\tilde{e}_1) < c'((\tilde{e}_1)$ and hence $\frac{d\tilde{g}_1}{d\delta} < \frac{d\bar{g}_1}{d\delta}$. There therefore exists a single value of $\delta$ such that for all higher values the upper boundary is preferable to an interior solution, and for all lower values the interior solution is preferable. We can show similarly that there exist a value $\delta^H_2$ such that the optimal solution has $b_l = \overline{b}$ if and only if $\delta \geq \delta^H_2$.

If $\delta \leq \delta^L$, then the supervisor and agent wish to maximize the surplus function $g_2(e) = g(e, \frac{1}{\alpha} \frac{\delta g_2(e)}{1-\delta} - \frac{1}{\alpha} \frac{\delta g_2(e)}{1-\delta} - c'(e))$ with respect to $e$ subject to the boundary conditions that $0 \leq b_l \leq \frac{1}{\alpha} \frac{\delta g_2(e)}{1-\delta}$. A similar analysis then gives us that there exist a value $\delta^H_2$ such that the optimal solution has $b_l = b_h$ if and only if $\delta \geq \delta^H_2$.

To define $\delta^H$, note that when when $\delta = \delta^L$ both cases apply, and hence it cannot be that $\delta^H_2 \leq \delta^L < \delta^H_1$. We therefore define $\delta^H = \min\{\delta_{H1}, \delta_{H2}\}$ and this then defines the high surplus case as stated in the proposition.

Finally, let us consider the relationship between $e$ and $\delta$. For high surplus contracts, $e$ is given by Lemma 3, i.e. $\frac{c'(e) + \alpha \overline{b}}{g(e, \overline{b}, \overline{b})} = \frac{\delta}{1-\delta}$. Differentiating the LHS with respect to $e$ gives us that $e$ is increasing in $\delta$ for high surplus contracts. Similar differentiations for contracts with low surplus, or intermediate surplus with $b_l = 0$, show that $e$ is increasing in $\delta$ for these cases.

For intermediate surplus optimal contracts with $b_l > 0$, we have $e = \tilde{e}_1$ where $g_1'(\tilde{e}_1) = 0$ and $g_1''(\tilde{e}_1) < 0$. Differentiating (4) by $e$ gives:

$$g_1''(\tilde{e}_1) = (1 - \delta) \frac{(1 - 2\alpha) c''(\tilde{e}_1) - (1 - \alpha)(1 - \tilde{e}_1) c'''(\tilde{e}_1)}{1-\delta - (1-\delta)\delta(1-\tilde{e}_1)}$$

Note that for this contract to be optimal we must have $1 - \delta - (1 - \alpha)\delta(1 - \tilde{e}_1) > 0$, since otherwise increasing $b_l$ and $s_l$ simultaneously relaxes ($IC - DE$). $g_1''(\tilde{e}_1) < 0$ therefore implies $(1 - 2\alpha) c''(\tilde{e}_1) - (1 - \alpha)(1 - \tilde{e}_1) c'''(\tilde{e}_1) < 0$. We then differentiate $g_1'(\tilde{e}_1) = 0$ implicitly by $\delta$ to obtain:

$$\frac{d\tilde{e}_1}{d\delta} = \frac{g_1'(\tilde{e}_1)}{(1-\delta)^2 ((1 - 2\alpha) c''(\tilde{e}_1) - (1 - \alpha)(1 - \tilde{e}_1) c'''(\tilde{e}_1))}$$

This expression is negative in any optimal intermediate contract with $b_l > 0$, and this thus completes the proof.
Proof of Proposition 2. We begin by considering how the principal should set parameters if she wishes to induce a contract with \( s_l = s_h \). We then show that inducing such a contract is indeed optimal.

The principal can induce a contract with \( s_l = s_h \) by setting \( \bar{b} = \frac{1}{\alpha} \frac{\delta g}{1-\delta} - b_l \), where \( b_l \) either takes the value 0, \( \bar{b} \) or a solution to (2). Note that \( \frac{d^2g_2(e)}{da^2} \geq 0 \) when \( g'_2(e) = 0 \), and hence there exists a value \( \hat{\alpha} \) such that the optimal contract will have \( b_l = 0 \) if and only if \( \alpha \geq \hat{\alpha} \). Moreover, \( \hat{\alpha} > 0 \) since at \( \alpha = 0 \) the supervisor and agent would clearly prefer setting \( b_l = b_h \). If parameters are such that \( b_l > 0 \), then the principal would prefer to increase \( \alpha \) since effort is increasing in \( \alpha \). Hence the principal will always set \( \alpha \geq \hat{\alpha} \). Since we then have \( c'(e) = \frac{\delta g}{1-\delta} + (1-\alpha)b \) and hence by increasing \( b \) and adjusting \( w \) to keep \( g \) constant the principal can increase effort without giving up extra surplus.

Proof of Proposition 3. The existence of \( \tilde{\beta} \in (0, 1) \) is straightforward.
Relational contracting is only a constraint in the no-delegation case when (1) does not hold at $e^{FB}$. When $e^{FB}$ is achievable without delegation, it is better for the principal not to delegate since delegation involves ceding surplus.

To show the existence of $\hat{\delta} \in (0, \bar{\delta})$, note that positive effort without delegation requires a value $e > 0$ that satisfies $ey - c(e) - \frac{1-\delta}{\delta} c'(e) \geq u + \pi$. Define $\overline{e}(\delta)$ as the value of $e$ that maximizes the LHS of this inequality for a given value of $\delta$. Then, since the LHS of this inequality is increasing in $\delta$, we can define $\hat{\delta} \in (0, \bar{\delta})$ to be such that $\overline{e}(\hat{\delta}) y - c(\overline{e}(\hat{\delta})) - \frac{1-\hat{\delta}}{\hat{\delta}} c'(\overline{e}(\hat{\delta})) = u + \pi$. In other words, $\hat{\delta}$ is the lowest value of $\delta$ such that there exists a relational contract sustaining positive effort without delegation.

For the principal to receive a payoff with delegation greater than their outside option, we require values of $e$ and $\alpha$ that lead to a positive value of the expression $ey - c(e) - \alpha \frac{1-\hat{\delta}}{\hat{\delta}} c'(e) - u - \pi$. With an appropriate value of $\alpha < 1$, the principal can induce effort $e = \overline{e}(\hat{\delta})$ at $\delta = \hat{\delta} - \epsilon$ to obtain a payoff of $c'(\overline{e}(\hat{\delta})) \left( \frac{1-\hat{\delta}}{\hat{\delta}} - \alpha \frac{1-\hat{\delta}-\epsilon}{\hat{\delta}-\epsilon} \right)$. Hence, for $\epsilon > 0$ sufficiently small, the principal can achieve a payoff greater than her outside option under delegation when $\delta = \hat{\delta} - \epsilon$. Since the principal cannot achieve a payoff greater than her outside option without delegation at this level of $\delta$, delegation is strictly preferable.
